Summary

Within ornamental horticulture context, visual quality of plants is a critical criterion for consumers looking for immediate decorative effect products. Studying links between architecture and its phenotypic plasticity in response to growing conditions and the resulting plant visual appearance represents an interesting lever to propose a new approach for managing product quality from specialized crops. Objectives of the present study were to determine whether architectural components may be identified across different growing conditions (1) to study the architectural development of a shrub over time; and (2) to predict sensory attributes data characterizing multiple visual traits of the plants. The approach addressed in this study stands on the sensory profile method using a recurrent blooming modern rose bush (*Rosa hybrida* 'Radrazz') presented in rotation using video stimuli. Plants were cultivated under a shading gradient in three distinct environments (natural conditions, under 55, and 75% shading net). Architecture and video of the plants were recorded during three stages, from 5 to 15 months after plant multiplication. Except for visual traits at the scale of the organs, panel performance was highly satisfying for most of the sensory attributes listed. Strong correlations (Spearman's coefficient ranging from 0.72 to 0.98) were found between them and architectural variables extracted from phytomer to plant scale data. Acceptable to very satisfying models were obtained (Q^2 ranged from 0.49 to 0.95, normalized RMSEP < 17.3%) with simple ordinary least squares regression and variable transformation to encompass non-linear relationships. The proposed approach presents therefore a powerful way to gain a better insight into the architecture of shrub plants together with their visual

Significance of this study

What is already known on this subject?

- Visual quality of ornamental plants is a key parameter playing a major role in the purchase triggering for consumers. Nonetheless, it is a complex notion based on the individual and subjective appreciation.

What are the new findings?

- A new method to studying and modeling the relationships between ornamental plant architecture and main visual components. The obtained models enabled to identify architectural variables with good predictive ability and especially relevant for explaining the visual appearance of the architecture of rose bush.

What is the expected impact on horticulture?

- Within ornamental horticulture context, visual quality of plants is an important criterion for consumers looking for immediate decorative effects products. This work will make it possible to objectify the relation between the architecture of the plant and the visual perception by the consumer. It's a future tool to help innovation in ornamental horticulture.

appearance to target processes of interest in order to optimize growing conditions or select the most fitting genotypes across breeding programs, with respect to contrasted consumer preferences.

Keywords

architectural analysis, linear regression, *Rosa hybrid*, sensory profile, visual appearance, woody ornamental plant

Introduction

Visual quality of ornamental plants is a key parameter playing a major role in the purchase triggering for consumers (Townsend-Brascamp and Marr, 1994; Schreiner et al., 2013; Ferrante et al., 2015). Nonetheless, it is a complex notion based on the individual and subjective appreciation of the product design or appearance by a given individual. Thus, preferences are mainly related to aesthetical judgments, although, for objective or subjective reasons, there may be differences or conflicts of judgment between people (Higginbotham, 1987; Creusen and Schoormans, 2005; Boumaza et al., 2010).

Effects of growing practices evaluated on various plant parameters measured with destructive or contactless methods are rather well-documented (Ferrante et al., 2015). Nonetheless, in such studies, a plant with pleasant visual appearance is too often seen as univocal and consumer preferences as homogeneous. Therefore even if manual or automatized grading occurs, actually the likeliness to observe a simple relation and good concordance between visual quality grades with specific preferences and expectations of the consumers, is small (Kohsel and Bennedsen, 2001; Garbez et al., 2016). From past decades, quality management of fresh horticultural products, especially fruits and vegetables, strongly benefited from the sensory evaluation science (Meilgaard et al., 2006). Its recent application on the rose bush showed also the strong relevance for providing a common background for objectifying and harmonizing visual quality studies on ornamental plants using real plants (Boumaza et al., 2009), single plant facet pictures (Boumaza et al., 2010; Huché-Théliér et al., 2011; Santagostini et al., 2014), and virtual plants presented in rotation on video (Garbez et al., 2015, 2016).

However, nowadays ornamental woody plants are still very often subjected to pruning or growth regulator applications to modulate plant growth for an empirical control of their quality. Knowledge about the variability of the architectural responses against environmental factors represents a valuable way to better control plant visual appearance with more reasoned, cheaper, and greener growing practices (Galopin et al., 2010; Huché-Théliér et al., 2011; Morel et al., 2012; Demotes-Mainard et al., 2013b; Crespel et al., 2014; Li-Marchetti et al., 2015). Understanding and controlling architecture is therefore an interesting lever to address ornamental plant design management, and more specifically to better fulfill expectations of the consumers thanks to knowledge about their requirements. Detecting links between architectural parameters and hedonic-free assessments of vi-

visual traits is thus needed to investigate if putative underlying key biological processes could be targeted. This approach, necessary to address visual quality of ornamental plants, cannot remain empirical. Thus, identification of visual attributes is necessary on the one hand to analyze their relations with the architectural components, the subject of this publication, and on the other hand to further understand the preferences of the consumers. However, literature about relations between perception of plant visual appearance traits and such architectural parameters for explaining consumer preferences is still poorly documented (Scuderi et al., 2012). First studies on rose bushes demonstrated the high potential of this approach through correlative studies either using young plants, or addressing for specific aims a limited number of visual descriptors selected from a sensory method or picked out from UPOV guideline for *Rosa* L. (Huché-Théliér et al., 2011; Crespel et al., 2013; Santagostini et al., 2014).

The main research objectives addressed in the present study concern (1) the architectural characterization over time of the rose bush without any pruning so that all the potential basal sprouts can be taken into account, and (2) if architectural components can be identified in relation to some visual traits and used for predicting them independently of plant age and growing conditions. The same rose bush cultivar was grown under three contrasted shading conditions to induce phenotypic variability. The architecture of the plants was recorded three times over 15 months of cultivation. In parallel, visual traits of the plants were characterized through a sensory profile trial using videos presenting them in rotation as stimuli. The paper presents: (1) the sensory profile of the plants on videos using multiple sensory attributes describing general aspects of the plants and their organs; (2) the architectural monitoring over the three acquisition stages, and the generation of plant-scale architectural variables; for (3) a correlation and ordinary least square regression study with the aim to predict the relevant and consensual sensory attributes using architectural variables as predictors.

Materials and methods

Plant material

The experiment used recurrent-flowering rose bushes from the Radrazz cultivar (*Rosa hybrida* L. 'Radrazz, marketed under Knock Out®) and light intensity as a means of inducing consequent phenotypic differences between plants. 'Radrazz' is a modern shrub cultivar. The flower is terminal,

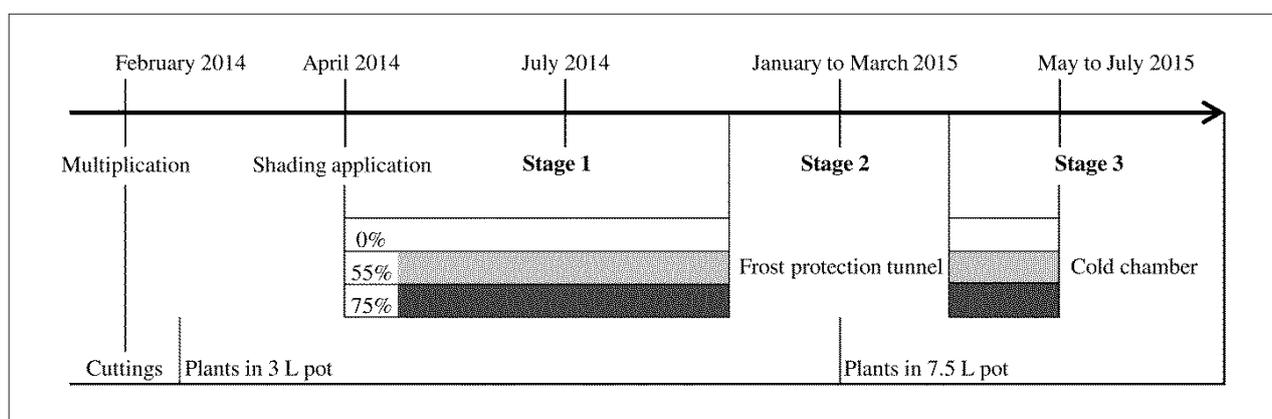

FIGURE 1. Schematic presentation of the container cultivation cultural conditions of 'Radrazz' rose bushes and stages of data acquisition periods.

solitary and simple, red to pink Bengali flowers – red45A, with determinate growth (Morel et al., 2009). Plants were obtained from single node cuttings harvested on the 4th February 2014 and individually placed in plugs for rooting as described in teammate protocols (Morel et al., 2012; Demotes-Mainard et al., 2013b).

Growth conditions

Plants were cultivated outdoors in pots under three shading levels in the experimental facilities of the IRHS (French Research Institute on Horticulture and Seeds, Angers, France; 47°28'45.8"N, 0°36'32.3"W, altitude 48 m).

As represented in Figure 1, experimental conditions started on the 25th April 2014, with young plants in 3-L pot, aged 81 days since cutting. Harvest was chosen as time reference for dating plant age. Sixty flowering and homogeneous plants intended to be characterized were randomly and evenly assigned in three environments on a soilless culture ground: (1) without shading screen (denoted 0%); (2) under

a tunnel covered with a 55%; or (3) 75% shading screen. The first year the plants were placed at a density of 1.1 plant m⁻². Then at mid-December 2014, plants were moved to an unheated polyethylene tunnel to prevent any frost damages on roots and future young shoots. Plants were then repotted in 7.5-L pot. Finally, plants were replaced on the 25th February 2015 to their respective environment at a lower density (0.8 plant m⁻²).

Plants were potted in a well-draining substrate (custom mix made by Faliénor; Vivy, France) composed of Irish peat, perlite, coir (50:40:10 in volume ratio), and fertilized with 1 kg m⁻³ of PG-Mix™ 14-16-18. Watering schedules of the three environments were individually adjusted according to rain, microclimatic conditions and substrate moisture status of the plants to guarantee no water limitation. Water was completed for fertigation with liquid 3:2:6 N-P₂O₅-K₂O ratio solution (Plant-Prod® 15-10-30; Plant Products, Leamington, ON, USA) with adjusted pH at 6.5 and EC at 1.2 mS cm⁻¹.

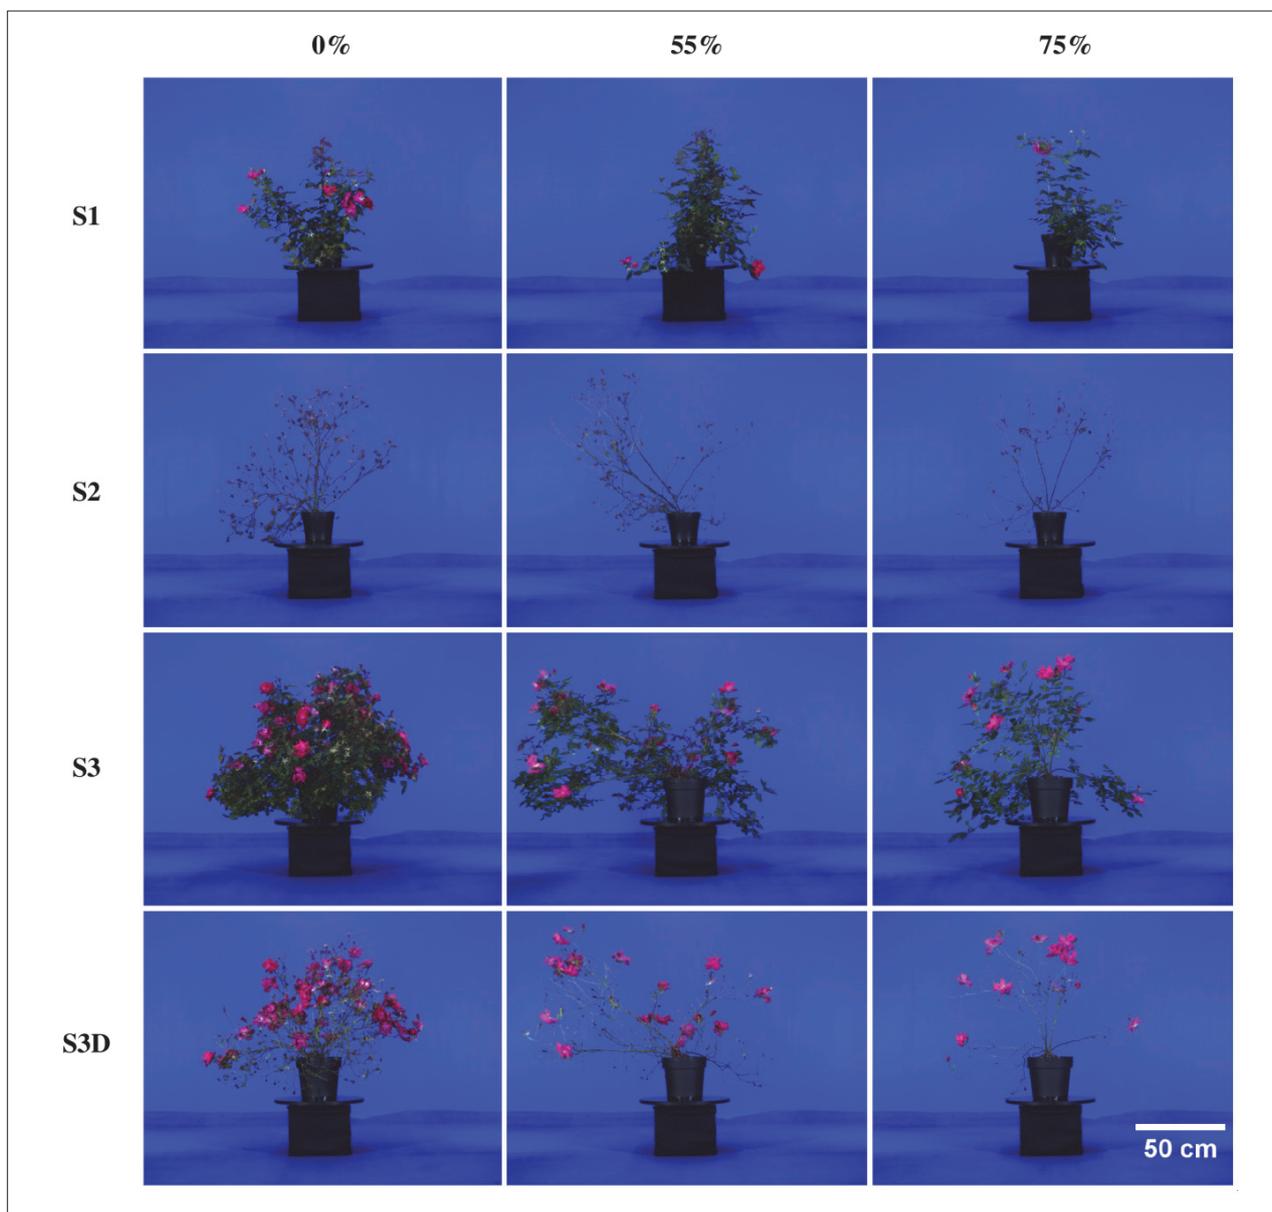

FIGURE 2. Panel of cropped and reduced size images of three rose bushes from the different shading environments (from left to right: 0, 55, and 75% of shading) over the three acquisition stages (from top to bottom: S1, S2, S3), then manually defoliated at the third stage (S3D).

Plant acquisitions

Tree times, a double characterization was realized during the 15 months: visual appearance, through a sensory profile using as stimuli rotating plant video edited from image sequences; and architecture, using a 3D magnetic digitizing contact method (Figure 1). For the three stages of development and the three shading environments, 179 rotating plant video and 132 plant architecture records were obtained for subsequent characterizations.

1. Image capture and editing of rotating plant videos.

A specific enclosure was set for capturing images sequences of potted plants in rotation. It was composed of a metallic structure (2.25 m height × 3 m width × 6 m length) covered with an occulting black fabric to avoid uncontrolled light variations, a blue photographic cloth (DynaSun, W003; Confidence Europe GmbH, Essen, Germany) for background, and a carpet of similar colour on the floor. Plant rotation and image capture were computationally controlled through a user-interfaced turntable (custom built device; Forumgraphic SA, Cassis, France). In order to obtain comparable images across data collection, system parameters were chosen and fixed for all the experiment duration testing the image capture on potted rose bushes of different ages from other experiments.

Center of the turntable (height of 30 cm) was placed at 1.4 m from the background, and 4.5 m from a front 12 bits 10Mpx CMOS colour camera (GigE UI-5490SE; IDS Imaging Development Systems GmbH, Obersulm, Germany) placed at 70 cm height from the floor. Focus was achieved with a standard zoom lens (Tevidon® 2/10; Docter Optics Components GmbH, Neustadt an der Orla, Germany). Scene illumination was controlled with daylight lamps (temperature colour ranging from 5500 to 6500 °K): four linear LED lamp lines in lateral position surrounding the turntable, two superior fluorescent tubes, and an annular LED lamp around the camera to enhance front lighting. Light variations in the scene were assessed and reduced using two-dimensional graphs of pixel intensities from the 'plot profile' function of ImageJ (Abràmoff et al., 2004) on greyscale images of the plant-less scene. Parameters for plant image sequence capture were set to: 360 images (resolution of 3840 × 2748) obtained along rotation intervals of one degree with break of seven seconds

for plant stabilization before image capturing. The time to capture a complete plant image sequence was thus fixed to 42 minutes. Before each sequence acquisition, the image of the blue background with the turntable and a plant-less pot filled with substrate was recorded for image analysis purposes.

Once the image sequences for the last stage (S3) were obtained (Figure 2), all the sequences were converted in AVI videos using ImageJ (Appendix A). Video parameters chosen were 3° between consecutive frames, thus 120 images per plant, with a frame rate of 10 frames s⁻¹ and JPEG compression.

2. Plant architecture recording. *Rosa* plants present stems with defined growth by terminal flowering (or abortion), and subsequent sympodial branching in all axes. For recurrent flowering varieties as 'Radrazz', axes are modules with continuous growth composed of phytomers edified by a single terminal meristem in which organogenesis ceases with autonomous floral induction (Zieslin and Mor, 1990; Le Bris et al., 1998; Morel et al., 2009; Costes et al., 2014). The phytomer is the basic structural and functional unit of vascular plant body. Generated by apical meristem of the shoots, the phytomers form the leafy axes by superposition, and higher order axes through branching resulting mostly from the outgrowth on node region of lateral bud(s) inserted at the leaf axil(s) (Barthélémy and Caraglio, 2007).

Plant architecture recording was done using the PiafDigit software (Donès et al., 2006). It consisted of encoding with a Fastrack® 3D digitizer (Polhemus, Colchester, VT, USA) the 3D coordinates of the phytomers constituting all apparent plant axes together with their topological relation (succession or branching) and some morphological features (Crespel et al., 2013; Morel et al., 2009, 2012; Li-Marchetti et al., 2015). Branching order notation followed the 'birth' organization of the axes, i.e., the first axis sprouting from the cutting was denoted as the 1st branching order, its lateral buds growth leading to second branching order axes and so on. This primary structure was labeled in this study as the 'elementary architectural system'. Proximal axes sprouting at or under the substrate level, sometimes called 'renewal canes' (Zieslin and Mor, 1981) and empirically seen as total reiterated complexes (Costes et al., 2014; Kawamura et al., 2015)

TABLE 1. Number of samples for architectural recording, image capture and video editing for each shading environment and for the three stages.

Stages Shading levels	Plant age	Video	Sensory	Architecture	Relation ¹
Stage 1	5 months	59	57	53	52: 36/16
0%		19	19	18	17: 12/5
55%		20	19	17	17: 12/5
75%		20	19	18	18: 12/6

75%		20	19	15	15: 10/5
Stage 3	15 months	60	57	33	33: 24/9
0%		20	19	11	11: 8/3
55%		20	19	11	11: 8/3
75%		20	19	11	11: 8/3
Total		179	171	132	130: 90/40

¹ First number indicates the number of plants characterized at both sensory and architectural levels; the second and third numbers separated by a slash detail respectively the number of observations used for calibration and for validation of the predictive models.

of an 'elementary architectural structure stage' (Crespel et al., 2013; Li-Marchetti et al., 2015), were denoted also as first branching order axes. These axes and all their descendants were further labeled as forming the 'delayed architectural systems'. Morphological features consistently recorded throughout the experiment consisted of reporting the apex state of the axes, and measuring with a digital caliper the basal diameter of each first branching order and the mid-length diameter for all the axes.

Plant characterizations

1. Visual characterization. Following an adaptation of Garbez et al. (2016) and Huché-Thélier et al. (2011), 171 different videos for the same 19 plants by shading environ-

ments, at the three acquisition dates (Table 1), were selected as the products to be visually characterized by a trained panel of 20 subjects according to a sensory profile approach derived from the quantitative descriptive analysis (QDA®) method (Stone et al., 1974). During the panel formation (10 hours divided into five sessions), 17 sensory attributes were elicited for describing the plants (Table 2): 12 were related to plant general aspect traits: the volume, the height, the width of the plant; the quantities of branching, quantity of leaves, flowers, fruits, and carrier axes; the growth habit, the shape uniformity, the shape balance, and lastly the plant density. Five other attributes described organ properties within the plant: the size and the colour of the leaves; the height of the flowers within the plant, the height of the veg-

TABLE 2. Sensory attribute definitions and panel performance indices. The first block of rows reports the consensual attributes with the best panel performance; the second reports those with unsatisfying performance indices highlighted in *italic* characters.

Sensory attribute	Definition	Repeatability ¹	Reproducibility ²	Consonance (%)	Discriminating power (F-ratio)
Flowers ³	Quantity of flowers: (0) no flower to (10) very high amount of flowers	0.54 ± 0.07	0.52 ± 0.46	93.2	15.5 ^{***}
Height	Plant height from collar: (1) very small to (10) very tall	0.60 ± 0.02	0.84 ± 0.15	88.4	55.5 ^{***}
Width	Plant width along rotation: (1) very thin to (10) very wide	0.71 ± 0.04	1.00 ± 0.18	76.9	8.1 ^{***}
Density	Plant density: (1) very loose, large and numerous holes within the plant silhouette to (10) very dense, any holes within the plant silhouette	0.71 ± 0.05	1.45 ± 0.32	69.6	7.5 ^{***}
Leaves ³	Quantity of leaves: (0) no leaf to (10) very high amount of leaves	0.76 ± 0.05	0.89 ± 0.49	79.4	8.1 ^{***}
Volume	Volume of the shape delimited by the plant contour: (1) very small to (10) very large volume	0.77 ± 0.04	1.03 ± 0.21	84.4	10.6 ^{***}
Carriers	Quantity of strong carriers axes: (0) no carrier axis to (10) very numerous carrier axes	0.79 ± 0.07	1.21 ± 0.23	72.3	8.1 ^{***}
Fruits	Quantity of fruits: (0) no fruit to (10) very high amount of fruits	0.80 ± 0.10	1.09 ± 0.35	83.4	12.8 ^{***}
Branching	Quantity of branches: (0) no branch to (10) very high amount of branches	0.82 ± 0.09	1.14 ± 0.25	78.4	4.0 ^{***}
Balance	Balance of the plant silhouette shape: (1) very unbalanced and dissymmetric to (10) very balanced plant evenly developed with constant shape along the rotation	0.93 ± 0.13	1.49 ± 0.29	65.2	10.6 ^{***}
Habit	Growth habit, shape elongation of the plant: (1) very spreading habit to (10) very upright habit	0.98 ± 0.07	1.09 ± 0.21	64.1	26.0 ^{***}
Flower height ³	Height of the flowers in the plant: (1) very down to (10) very high in the plant	0.77 ± 0.07	0.68 ± 0.66	77.9	43.6 ^{***}
Growth height	Height of the growth organs (axes or both axes and leaves if present) in the plant: (1) very down in the plant to (10) very high in the plant	0.83 ± 0.10	0.88 ± 0.35	42.5	6.3 ^{***}
Leaf size ³	Average size of the leaves: (1) very small to (10) very large leaves	0.88 ± 0.10	1.02 ± 0.52	36.3	6.9 ^{***}
Leaf colour ³	Green darkness of mature leaves: (1) very clear to (10) very dark leaves	0.93 ± 0.08	1.32 ± 0.54	53.3	3.2 ^{***}
Flower clustering ³	Proximity of the flowers: (1) not particularly grouped, very homogeneously distributed in the plant to (10) flowers forming only one distinct cluster	1.12 ± 0.13	0.89 ± 0.90	82.4	39.7 ^{***}
Uniformity	Complexity of the plant shape formed by the growth organs: (1) very irregular with several distinct blocks to (10) very regular forming an indivisible shape	1.17 ± 0.12	1.66 ± 0.37	60.8	9.0 ^{***}

¹ Values are means ± standard errors over the 8 duplicated videos of the pooled standard deviations of the subject scores between replications.

² Values are means ± standard errors over the 171 different videos of the standard deviations of the subject scores.

³ Attributes for which the score 0 means no corresponding organ in the plant, and thus for which videos of the plants during winter rest (Stage 2) were not considered for consonance and discriminating power assessments.

etative organs (leaf and axes, or axes only) within the plant, and the clustering of the flowers. All the 171 products and four duplicates for repeatability controls, next to 31 other plant videos used for another purpose not dealt with here, were scored upon the 17 attributes on paper sheets by the 20 subjects in 8 scoring sessions of an hour in average (25 to 27 videos to score per subject and session). Formation and scoring sessions took place in a computer lab with identical LCD monitors in standard mode configuration with optimal preset 1920 × 1080 resolution, and situated to avoid communication between subjects. Subjects were not informed about cultural conditions and ages of the plants. All the videos and their duplicates were anonymized with three-digit number codes. Thus for each plant, the videos presenting respectively its three acquisition stages can also be considered as three different plants.

To limit the task difficulty for the panelists, scoring sessions consisted in the characterization of two out of three consecutive batches of videos: a first batch formed with

plants presenting leaves and flowers (S1 and S3 pooled), and a second formed either with videos of plants during rest phase (S2) or with flowering plants before manual defoliation after the image acquisition for S3 and not dealt with here (Figure 2). Videos were presented using VLC media player (VideoLAN project, France) and individual playlist scripts according to an optimal design based on a William's Latin square adaptation and randomization to prevent any order effect.

Performance of the panel for each sensory attribute was assessed with common approaches presented in previous studies using rose bushes (Boumazza et al., 2010; Huché-Théliér et al., 2011; Santagostini et al., 2014; Garbez et al., 2015). Repeatability and reproducibility (Rossi, 2001) of average measurements over products were used respectively to assess the ability of the subjects to score consistently for the duplicated videos, and to score the products as the other panel subjects. The agreement between subjects was analyzed through principal component analysis (PCA),

TABLE 3. Standardized principal component analysis of weighted determined axis pooled observations ($n = 33,690$) with axis-scale data extracted from plant architectures recorded during all the experiment. The first block of rows reports quantitative variables and Pearson correlations with principal components (PC) if not negligible (N if $r_p < 0.3$ in absolute value). The second block reports variables characterizing the axes and conditions treated as supplementary qualitative data with eta-squared indices measuring the proportion of variance explained on PC.

Data type – Variable	Category	PC fulfilling Kaiser criterion and variance explained (%)

Plant	Condition	0.01	0.05	0.09

¹ Computed as the ratio between length of the portion from the base of the bearing axis to the insertion point of the axis in question and the total length of the bearer. It thus tends to 0 if the axis is a basal branching and to 1 if it is apical one. The ratio was set to 0 for all the branching order 1 axes.

² Computed as 1 minus the ratio between axis cord length: the axis cord is the straight line from the base to the extremity of the axis; and the axis length. It thus equal to 1 for axes completely recurved, and tends to 0 for straight axes.

³ Distances are computed from the plant collar to the point mentioned in the variable name.

⁴ Not considered in the multivariate analysis since azimuth of the axes cannot be individually compared between plants, but only extracted for plant-scale variables.

⁵ Not considered in the multivariate analysis since it only concerned the first branching order axes, but extracted for plant-scale variables.

with subjects as columns and products as rows, to highlight outlying subjects and compute a consonance measurement of the scores as the variance accounted for the first PC (Dijksterhuis, 1995). Finally, score differences between products were assessed by four-way mixed analysis of variance (ANOVA) modeling (Kuznetsova et al., 2015). The analysis model included the subjects as a random factor with stages and shading environments as fixed factors, plants as a nested and fixed factor within shading environments, and their interactions. Significance of the score differences between products was used to evaluate the discriminating power of the attributes and the global panel performance. This was tested through the effect on scores of the three-way interaction between plants in shading levels and stages. Discussions were undertaken for discarding attributes for which the panel performance components were eventually judged as not sufficient. Then, PCA of the 'products × attributes' matrix of average scores was carried out to achieve a synthetic description of the relationships between the attributes, and of the visual characteristics of the plants presented on videos.

2. Architectural characterization for generating plant architectural descriptors. Architectural records were converted into MTG files (Multi-scale Tree Graph; Godin and Caraglio, 1998) through PiafDigit for extracting axis-scale variables using the *amlPy* interface module under the OpenAlea platform (Bonnard and Pradal, 2008; Pradal et al., 2008; Morel et al., 2009; Crespel et al., 2013). Variables extracted concerned the morphology, the topology and the geometry of the axes complemented with experimental information (plant index, shading level and stage of acquisition; Table 3).

Effectiveness of the architectural differences between the shading treatments over stages was assessed considering the determined axis observations, i.e., the axes which organogenesis has been stopped by floral transformation of their apex. Blind shoots were considered as determined axes too since apical meristem abortion also implies the arrest of the axis organogenesis. Branching (number of axes) and organogenesis (number of phytomers) were analyzed separately by mixed ANOVA modeling and Bonferroni's correction method for post hoc tests with error level $\alpha=0.05$. Models included stages and shading environments as fixed factors, plants as a nested random factor within the shading environments, and their interactions.

Extracted axis-scale variables were then subjected to PCA to analyze major variation sources between determined axis observations (Morel et al., 2009), and further used to generate a database of plant-scale variables that can be potentially related to the studied visual traits. Plant-scale variables selected by Crespel et al. (2013) and used in Li-Marchetti et al. (2015) were straightforwardly extracted for comparison purposes. Other variables integrating axis-scale variables at the plant level were defined with descriptive statistics such as sum, mean, median, quantiles, ranges, empirical standard deviation, minimum, maximum and coefficient of variation, according to the relevance of their use. The most important quantitative axis-scale variable highlighted by PCA was used to generate a supplementary qualitative variable determined from comparative analysis of different clustering and validation approaches. This qualitative variable was used like the branching order and the apex state to generate other more detailed variables. In parallel, the 3D coordinates of phytomers were extracted from the MTG files to be analyzed individually as 3D point clouds under the R environment (R Development Core Team, 2015). Ba-

sic functions as for integration of the axis-scale variables enabled the computation of other features at whole-plant scale, such as landmark coordinates, metric distances, and spatial variances characterizing the phytomer cloud of the plants. In addition, volumetric estimation of the plants was obtained through computing the 3D convex hull volume enclosing the phytomers using the *alphahull R* package (Pateiro-López and Rodriguez-Casal, 2010). Finally, the database integrated also some complementary variables built on previous ones. Thus, more than a thousand plant-scale architecture-based variables ($p=1,209$) were collected and available as potential predictors for relationship study with the sensory attributes (categorization of the variables and examples in Table 4).

3. Relating visual and architectural characterizations.

Out of the 171 products characterized by sensory profile, 130 corresponding plant architecture recordings were available (Table 1). Sensory attribute variables were defined as the average scores of the subjects by product and analyzed conjointly with plant-scale architectural descriptors. Links between pairs of sensory attribute variables and plant architectural descriptors were first evaluated with Spearman's correlation coefficient (r_s) to detect eventual monotonic relationships (Huché-Théliér et al., 2011; Santagostini et al., 2014). Then, prediction of the sensory attributes variables was tested with simple linear regression through ordinary least squares (OLS), the most common and simple regression method (Næs et al., 2011; Kuhn and Johnson, 2013), using the plant architectural descriptors as potential predictors one by one without any stage- or shading-based parameters.

In order to assess their relevance and genericity, the models were first calibrated through 10 repeats of 10-folds cross-validation on two-thirds of the data ($n=90$ plants observations over stages and shading environments), and then validated on the remaining third (Borra and Di Ciaccio, 2010; Kuhn and Johnson, 2013). Data partitioning was the same for all the sensory attributes, i.e., with a balanced-based design according to stages and shading environments with a 2:1 ratio random sampling within all the 9 crossed conditions (Table 1). Goodness of fit was evaluated with the traditional coefficient of determination and lack of fit with the root mean square error for the entire calibration data (respectively R^2 and RMSE), and through 10-10 folds cross-validation (respectively R_{CV}^2 and $RMSE_{CV}$). Coefficients of determination and root mean square error of prediction computed from the validation dataset (respectively Q^2 and RMSEP) were then used to assess the predictive ability of the models with unknown data. Common transformations (power, root, log, exponential and inverse) and normality supervised power-transformations of Yeo-Johnson were applied to the predictors (Yeo and Johnson, 2000) with the aim to better satisfy required linear modeling assumptions (Kuhn and Johnson, 2013) while exploiting more deeply the data still using a relatively simple modeling approach.

Statistical analyses

Statistical analyses were conducted under the R environment (R Development Core Team, 2015) with additional functions from the packages detailed thereafter. PCA were conducted with *FactoMineR* (Husson et al., 2016) using centered and scaled data. Variable discretization was performed with *classInt* (Bivand et al., 2015), by increasing number of classes through k-means (Steinley, 2006) and Fisher-Jenks algorithms (Murray and Shyy, 2000; Anchang et al., 2016). Quality and stability of the solutions were assessed using elbow graphical method, clusterwise Jaccard similarity sta-

tistics under bootstrap resampling with *fpc* (Hennig, 2008, 2015), and Davies-Bouldin cluster separation measurements (Davies and Bouldin, 1979) with *clusterSim* (Walesiak and Dudek, 2015). Mixed models were designed using *lme4* (Bates et al., 2016) and analyzed with ANOVA function of *car* (Fox et al., 2016) with type II sums of squares procedure (Langsrud, 2003). Subsequent multiple comparisons

were done according to the Bonferroni's adjustment method on least-squares means from *lsmeans* (Lenth, 2016). When required, Kenward-Roger's degrees of freedom estimations were used for statistical inferences (Spilke et al., 2005; Kuznetsova et al., 2015). Data partitioning and modeling between sensory and architectural data were done using *caret* (Kuhn, 2016).

TABLE 4. Examples of architectural variables at plant-scale gathered according to methods used and description categories proposed from the 1209 variables extracted.

Method/Category	Examples of variables																				
Direct integration of the axis-scale variables																					
Morphology	Number of axes, Cumulated number of phytomers																				
	Number of open flowers, Number of dry fruits, Number of open and faded flowers																				
	Proportion of flowering axes, Proportion of vegetative axes																				
	Cumulated number of phytomers of the determined axes																				
	Cumulated length of the vegetative axes																				
Topology	Mean number of branched nodes, Mean length, Mean diameter at median length																				
	Mean length of the axes ended by a fresh to dry fruit																				
	Number of 1 st branching order axes																				
Geometry	Maximum branching order																				
	Mean branching order																				
	Mean relative location of branching insertion for the 2 nd branching order axes																				
	Mean cord angle, Mean lateral distance																				
	Median lateral distance																				
	Quantile 5% of the cord angle																				
	Coefficient of variation of the lateral distance																				
	Standard deviation of vertical distance																				
Axis length clustering																					
	Number of axes per identified length class ¹ , summary statistics detailed thereafter

	Mean curvature of the 1 st and 2 nd branching order long axes																				
	Interquartile range of the azimuth of the long and medium axes																				
	Range of the cord angle of the medium axes																				
	Maximum width divided by maximum height																				

¹ Fisher-Jenks and k-means algorithms assessed for addressing the axis length clustering led to the same results.

Results

Visual characterization

All the attributes were significantly discriminant (the product effect, *i.e.* the interaction 'plant : shading : stage', was highly significant with p -value < 0.001) indicating thus a relatively acceptable global panel performance (Table 2). Means and standard errors of repeatability measurements for all the attributes except 'uniformity' and 'flower clustering' were relatively low and not so variable (maximum $M = 1.17$ and maximum $SE = 0.13$), indicating very little and similar differences of the subject scores over duplicated videos. Reproducibility measurements indicated that differences between subject scores on same videos were also rather low and stable except for 'uniformity', 'flower clustering', 'flower height', 'leaf colour', and 'leaf size' (M over 1.50; SE over 0.50), indicating more relative differences between subject scores on same videos, eventually coupled with difference inconsistencies between the videos and the subjects. Finally, acceptable to very high consonance measurements confirmed with previous results the very good performance and consensual appropriation of the 11 other attributes out the 17 (Table 2).

Principal component analysis (PCA) of the average score matrix for the 171 products and the 11 selected sensory attributes allowed to identify some relations between visual characteristics, and to highlight how they structured the plants throughout shading environments and vegetation stages (Figure 3). Four principal components (PC) were considered according to the Kaiser criterion, which explained 93.4% of the overall variance. However the first plan accounted for 70.9% and was sufficient to well discriminate main characteristics of the plants within stages and shading environments. Globally, PC1 and PC2 structured the plants according to V-shaped patterns separating the plants characteristics chronologically, and then with large to more subtle differences between shading levels. PC1 (45.8% of the variance) synthesized plant dimensions, branching and shape equilibrium over stages, with the shading level diminution. Not surprisingly, it reflected very high to moderate correla-

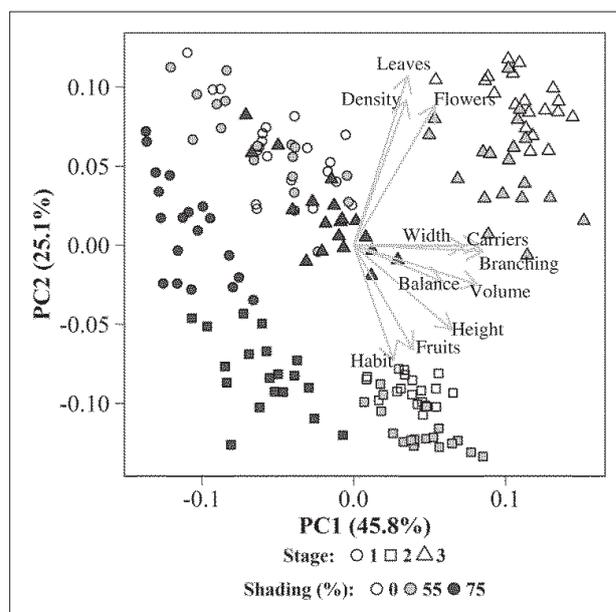

FIGURE 3. Biplot of the standardized principal component (PC) analysis of the mean 'product × attributes' matrix. The 171 plant videos being the products (rows) are plotted using grayscale shades for shading environments, and symbols for acquisition stages. The arrows indicate the direction of the 11 sensory attributes (the columns, defined as average subject scores by product).

tions between 'branching' and 'carriers', 'volume', 'width', and 'height', and then 'balance'. Highest Pearson correlations for 'balance' were with carriers ($r_p = 0.62$) and branching ($r_p = 0.60$) which presented the strongest association ($r_p = 0.92$) between all attributes pairs. Plant characteristics were essentially structured by age and sub-structured by shading level diminution. Interestingly, scores for plants grown under 75% of shade were systematically lower than those grown

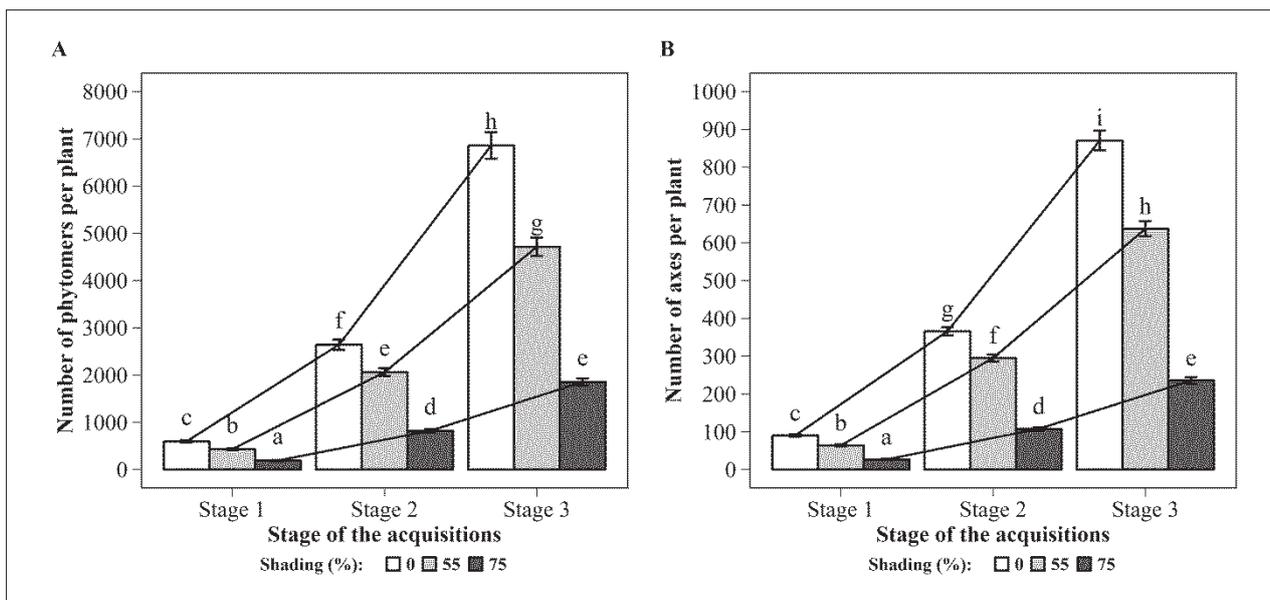

FIGURE 4. Whole-plant organogenesis (A) and branching (B) considering determined axis observations across shading levels and over stages. Values are least-squares mean estimates with standard errors obtained from generalized linear mixed models with Poisson distribution of measurements made on $n = 11$ to 18 plants, for a total of $N = 132$ plant architecture records. Different letters indicate significant differences detected with the Bonferroni's post hoc test (error level $\alpha = 0.05$).

under 0 and 55% which were more similar. PC2 (25.1%) strongly reflected the expected very high correlation between 'leaves' and 'flowers', and their respective high and moderate correlation with plant density. PC2 opposed those attributes to 'fruits' and 'habit' presenting a negligible correlation ($r_p = 0.25$), and 'height' also moderately reflected on PC2, with the strongest correlation observed between 'fruits' and 'leaves' but with a low opposition link ($r_p = -0.42$). It thus showed a structuration of the products according to the presence or absence of leaves and flowers, separating, as expected, S1 and S3 far from S2 plant characteristics. Then, it showed also a sub-structuration within stage groups according to the quantity of leaves and flowers for S1 and S3; and according to density, habit, fruits and height for the three stages enabling to separate the three shading levels for their characteristics at S2 and S3. However, it only separated plants grown under the highest shading level at S1.

Thus, the subjects were able to detect various noticeable visual differences easily explainable by shading and plant age. However the large to moderate inertia observed (Figure 3) within the shading environments at each stage indicated that various within-crop visual differences between plants were perceptible. Thus subsequent relations between architecture and visual appearance were addressed considering the videos with their corresponding recorded plant architecture, as different plant observations for taking in account all the observed variability.

Architectural characterization

Throughout the three stages, 41,341 axis observations were collected; some axes being eventually observed up to three times; 81.5% of the observations concerned determined axes with 21.7% of them being blind shoot observations, 18.3% were for vegetative axes and 0.2% were unclassified. In average, number of determined axes and their number of phytomers per plant presented similarly a decrease according to shading intensity, with respective increase over stages, while respective variations increased with plant development (Figure 4). Poisson distributions with log-link function, often more adapted for count data modeling, enabled to circumvent assumption violations observed with linear modeling. Models fitted well the data at hand (over dispersion Chi-square tests both presented $p < 0.001$), and both were highly relevant and presented low effects from plants as suggested by conditional and marginal R^2 , both over 0.97 for the two models (Nakagawa and Schielzeth, 2013). For both the two variables, deviance table analyses confirmed the significant effects from stage and shading, as their interaction (Wald Chi-square test p -values < 0.001), and 95% confidence interval of the variance accounted by the plants within shading environments revealed that, event low, the effects from plants were significant. Results reflected the influence of the light intensity for plant development through both organogenesis and branching processes of the primary growth.

Clustering approaches used for the analysis of the length of the axes, chosen for its larger variance and constancy of the metric unit (contrarily to phytomer length), suggested that, when considering the experimental conditions separately (data not shown) or pooled, an optimal and consistent solution was obtained with 4 classes. Identified classes, latter respectively called: tiny, short, medium, and long axes which characteristics for the determined axis observations are presented within Table 4, were observed in all the plants whatever the stage and the shading level. Interestingly rela-

TABLE 5. Spearman correlation matrix between sensory attributes (columns) and respective architectural plant-scale variables (rows) the most correlated thereto for the entire dataset (N = 130 plant videos). Bold values indicate the most correlated architectural variable to each sensory attribute.

BO: Branching Order followed by the level, BO1: first branching order.

tive distribution of the classes according to branching orders and the two types of architectural systems used (elementary versus delayed) highlighted a recurrent and rather stable pattern in the three shading environments and over stages. Notably, the first axis of the cuttings was medium, carrying long, medium, short and tiny axes, while the first branching orders of the delayed architectural systems in almost all the observations were long axes.

Then, before generating the plant-scale architectural variables used thereafter, length classes were attributed to the vegetative axes for consistency in the database, and since they were present on the plants characterized by the panel.

Relating visual and architectural characterizations

Significant high to very high correlations were found for all the sensory attributes with at least one architectural plant-scale variable (Table 5). Very strong relations were found for the attributes assessing quantity and metric traits, the smallest Spearman's correlation coefficient (r_s) was 0.92 between 'carriers' and the number of long and medium axes up to the third branching order; and the highest was 0.98 between 'flowers' and the number of floral buds with petal colour visible and open flowers. Lower but still high correlations, ranging from 0.72 to 0.78, were found for 'balance', 'density', and 'habit'. While correlations of the architectural variables the most related to 'habit' and 'balance' with the other attributes were indeed lower, the cumulated length of the axes ended by a floral bud to an open flower was much more correlated to 'flowers' and 'leaves' than with 'density'. Overall, similar correlations were found for the same attributes with different variables and on the opposite, especially with the variables related to 'flowers', 'leaves', and 'density'; to 'carriers' and 'branching'; then to 'volume', 'width', and 'height'.

Correlations do not imply causations and may vary considering the sub-samples studied. Thereby, cross-validation on calibration data and validation on unknown data undertaken using OLS models with predictor transformations enabled the predictive efficiency of the available plant-scale

architectural variables to be assessed more robustly. Table 6 summarizing the statistics of the models minimizing the prediction error with unknown data (RMSEP) showed that the most correlated architectural variables highlighted previously were not necessarily those leading to the best models, and that non-linear relationships were in most cases much more adapted. Overall, predictive abilities of the models obtained were quite remarkable especially for the sensory attributes related to metric and quantity traits. The less accurate model presented a relative error of prediction that did not exceeded 17.3%, corresponding to the range normalized RMSEP of 1.09 for the attribute 'balance'. Models with lesser performances in prediction were obtained for 'density', 'habit', and 'balance', suggesting potential links between panel performance for the sensory attributes and predictive abilities of the models that can be expected.

Discussion

Light modulation through shading enabled to induce phenotypic plasticity for the architecture of the 'Radrazz' rose bush. As already highlighted and especially exploited for the production of cut roses, results confirm the strong influence of light on the rose architecture, especially for its initial signal role in the regulation and expression of the process related to organogenesis and branching. (Zieslin and Mor, 1990; Crespel et al., 2014; Leduc et al., 2014).

From ecological and botanical points of view, results strengthen observations made about the large phenotypic plasticity of shrubs, often in response to light gradients, enabling them to adopt highly contrasted architectural development strategies according to local conditions (Valladares et al., 2000; Kawamura and Takeda, 2002, 2004; Percy et al., 2005; Charles-Dominique et al., 2010, 2012, 2015; Charles-Dominique, 2012; Sterck et al., 2013; Guzmán and Cordero, 2016).

This study allows to analyze the architectural of the 'Radrazz' rose bush and more broadly to provide information on the architectural development of shrubs throughout their life cycle. To resume the observed variability between axes

and for predicting branching and carrying branch amounts, present results highlighted the relevance of the axis length based segmentation proposed, e.g., as used for apple tree architecture phenotyping and modeling (Costes et al., 2003; Pallas et al., 2016). Indeed, with age, delayed branching (proleptic), which is discernible by little scaly phytomers at the basis of the axes, is more and more prevalent within plants. The contrasted plants obtained with the shading experiment design, complementary results showed that this axis-length-based segmentation provided a quite stable pattern for the axis length distribution closely linked to branching orders within plants. Most of the basal sprouts leading to the architectural systems here labeled as 'delayed' were carried by longer axes, well supporting the first part of the definition for reiteration summarized in Costes et al. (2014): a shoot with a comparable or longer length than its parent shoot and that partially or totally repeats the parental branching system. However, together with length, the orientation of the first branching order axes suggest quite different functions and different profiles between shading conditions. Supporting the reiteration definition with respect to the architectural unit and its total reiteration concepts (Barthélémy and Caraglio, 2007), quite relevant for tree life cycle (Raimbault and Tanguy, 1993; Fay, 2002; Ishii et al., 2007), seems thus to present some inconsistencies for transposing the pattern and terminology used for trees to the rose bush and more generally to shrubs (Barthélémy and Caraglio, 2007; Y. Caraglio and G. Galopin, pers. commun.). Indeed, to observe plainly the Champagnat model (Hallé et al., 1978; Costes et al., 2014), 'Radrazz' has to develop relay and renewal shoots, seen up to now as reiterated complexes, but quite different from the 'elementary architectural structure stage' (Crespel et al., 2013; Li-Marchetti et al., 2015) and its development. Nonetheless, by definition, total reiteration does not lead to newest axis categories and thus should not be integrated to define neither the architectural model, nor the architectural unit. Similar observations led to revisit the Tomlinson model for basitonic branching plants (Cremers and Edelin, 1995). We may ask if the reiteration process for shrub plants should be revisited or refined to integrate the hypothesis that this process may be necessary to the architectural unit construction ('establishment phase', see Barthélémy and Caraglio, 2007) rather than a duplication of the first primary axis. Future analysis of the data using Hidden Markov chains Tree (HMT) model (Durand et al., 2005) together with similarity and distance indices between tree-structured data (Ferraro and Godin, 2000, 2003; Segura et al., 2008) to investigate finely the typology of the axes together with their topology and mutual matching may enable addressing more deeply such a hypothesis to further propose more relevant concepts for the life cycle pattern of shrubs forming bushes.

The study demonstrated the relevance of the method proposed for studying the relationships between plant architecture and main visual components. Video stands enabled the avoidance of all possible product alteration during sensory tasks, especially critical for the state of the flowers. During panel formation, 17 sensory attributes were finally proposed. They were not all strictly similar but very close and coherent with the vocabulary and attributes highlighted for virtual 'Radrazz' rose bushes assessed using video (Garbez et al., 2015, 2016), or for real ones assessed directly or using unique plant facet photographs (Boumaza et al., 2009, 2010; Huché-Thélier et al., 2011; Santagostini et al., 2014). Among the 17 sensory attributes, the panel performance was good enough for 11 of them. Consensual attributes were

related to plant size, plant shape, and quantification of the organs. The six other attributes not considered here are not uninteresting so far. They may be more suitable and relevant for studying other cultivars than 'Radrazz', or for experiments with other cultural practices. Besides, enhancing panel training with more precise protocol notation, definitions, and product references for the attributes and practice scaling test tasks with feedback for calibration is highly recommended (Rainey, 1986; Wolters and Allchurch, 1994; Labbe et al., 2004; Findlay et al., 2007). Furthermore, multiple methods to present the stimuli may be investigated. For example, presenting organs *ex-planta* on static images as stimuli for assessing characteristics at the organ scale such as 'leaf size', or also 'flower colour intensity' or 'flower size' not investigated here, may be thus more efficient for the characterizations at the organs scale.

Finally, results obtained previously using virtual rose bush videos were confirmed with real plant material, with the validation of a protocol (number of videos, scoring sessions, and number of subjects). The obtained models enabled us to identify architectural variables with good predictive ability and especially relevant for explaining the visual appearance of the architecture of the rose bush. They reflected branching, growth and sexual expression of the axes as their structure in space, especially critical in the architectural establishment of the rose bush. Such variables enabled here the characterization of the plants cultivated under three contrasted shading environments with a reduced and coherent set of features over time. The large number of architectural variables that can be obtained, as here considering the methodological choice made, led to numerous comparable predictive models with quite acceptable results for each sensory attribute. Such results should thus lead researchers to carefully address the relevance of the variables selected from biological and practical viewpoints, and thus investigate more specific analyses, merging expert knowledge and advanced statistical methods adapted to variable selection and modeling under the ' $n < p$ ' conditions (Zucchini, 2000; Kuhn and Johnson, 2013; Silva et al., 2013) as illustrated previously with virtual rose bush and predictive image analysis-based models (Garbez et al., 2016). Upcoming analyses will address on the real plants the relevance of this previously tested image analysis method with more elaborated predictive modeling procedures, which may present relevant results, especially for sensory attributes concerning complex multidimensional visual traits, as here with the plant growth habit, its density and its balance. Improvements in the approach may concern image (size and resolution) and scene management for video editing in order to provide the most fitting plant visualization. Comparing results obtained from same plants presented using different stands is nevertheless necessary to gain more precise insights in the visual perception of ornamental plants.
